Abstract. In this paper we show that changing from an ion temperature gradient (ITG) to trapped electron mode (TEM) dominant turbulence regime (based on linear gyrokinetic simulations) results experimentally in a strong density pump-out in low collisionality, low power H-mode plasmas. We vary the turbulence drive by changing the heating from pre-dominantly ion heated using neutral beam injection
to electron heated using electron cyclotron heating, which changes the $T_e/T_i$ ratio and the temperature gradients. Perturbed gas puff experiments show an increase in transport outside $\rho = 0.6$, through a strong increase in the perturbed diffusion coefficient and a decrease in the inward pinch. Linear gyrokinetic simulations with TGLF show an increase in the particle flux outside the mid-radius. In conjunction an increase in intermediate-scale length density fluctuations is observed, which indicates an increase in turbulence intensity at typical TEM wavelengths. However, although the experimental changes in particle transport agree with a change from ITG to TEM turbulence regimes, we do not observe a reduction in the core rotation at mid-radius, nor a rotation reversal.
1. Introduction

Through control of the density gradient, particle confinement can affect the fusion power in ITER [1] and the underlying turbulent modes. Despite its importance, our understanding of particle transport lags behind heat transport. As a result, current predictions for ITER conservatively assume a flat density profile in the core [2]. More optimistically, a peaked density profile may be obtained by operating at low collisionality [3]. However, recent work has shown that in a set of self-similarity experiments in which only collisionality was altered, no increase in density peaking was observed, in agreement with gyro-kinetic simulations [4]. So the focus is shifting from collisionality to the role of turbulence and toroidal rotation in determining particle transport [5]. In this paper we will study the effects of the underlying turbulence structure on particle transport in low torque, low collisionality H-modes on DIII-D.

In order to study the effect of turbulence on particle transport in the DIII-D tokamak we performed a set of experiments in which the heating power is altered from predominantly ion heating [using the neutral beam injection (NBI) system] to electron heating [using electron cyclotron heating (ECH)]. In DIII-D the ion-electron collisional coupling is weak enough, that in low collisionality (ν* ∼ 0.2) discharges switching from ion to electron heating alters both temperature gradients and thus the turbulence drive in the core plasma. We observe in ECH-heated plasmas a strong reduction in the density profile over the whole plasma radius. This is in sharp contrast with experiments on AUG, where adding ECH to change the temperature gradients and turbulence drive results in a more peaked density profile [5].

Turbulence in a tokamak plasma is gradient driven. In predominantly ion heated plasmas, the ion temperature gradient (ITG) drive will be dominant, whereas in plasmas that are dominantly electron heated, the electron temperature gradient becomes the driving force. This results in a switch to trapped electron mode (TEM) driven turbulence. The TEM mode depends on the electron temperature gradient as well as the electron density gradient. Theory predicts that changing from dominantly ITG to TEM turbulence regimes results in the reversal of the group velocity of the turbulent structures from the ion to the electron direction [6]. This will then result in the reversal of the intrinsic rotation component of the toroidal rotation, which in a torque free plasma leads to a rotation reversal of the toroidal rotation [6]. The sign change of the turbulence group velocity also changes the thermodiffusion component of the particle flux from an inward (ITG) to outward flux (TEM) [7]. Experimentally the picture with relation to particle and momentum transport is more complicated. There is a large body of work that links toroidal rotation reversals with linear ITG-TEM transitions, however more experimental observations find that rotation reversals can also occur without a
change in local gradients and thus without a change in the calculated linear turbulence regime [8, 9, 10, 11, 12].

In this paper we do observe a change in linear stability from ITG to TEM, but we do not observe a rotation reversal. We do however observe a change in particle transport and an overall reduction of the density profile from particle balance analysis. Perturbed gas puff experiments show an increase in the particle transport outside $\rho \sim 0.6$ (with $\rho$ being defined as the square root of the poloidal flux). This is in agreement with quasi-linear modeling using the TGLF transport model, which shows that particle transport does not change much around mid-radius, but increases significantly at $\rho \sim 0.74$ in the ECH heated plasmas. Mid-scale density fluctuations increase from mid-radius and outward for the TEM unstable plasmas. All these results point to a strong increase in particle transport in the outer half of the plasma. In the discussion we will compare our results to previous results from other tokamaks with relation to particle transport.

2. Experimental setup

These experiments in DIII-D [13] focus on low power (3–4 MW) low normalized plasma pressure, $\beta_N \sim 1–1.5$ H-mode plasmas in the ITER Similar Shape (ISS) at a $q_{95} \sim 4.2$, plasma current, $I_p = 1.1$ MA, toroidal magnetic field, $B_T = 1.9$ T, with zero and low co-torque (0.5 N-m) injection from the NBI system. This allows us to avoid locked modes and still operate at a low line averaged electron density $n_e \sim 2–4 \times 10^{19}$ m$^{-3}$. This results in a collisionality of $\nu^* = q_{95} R \epsilon^{-3/2} \lambda_e^{-1} \sim 0.2 – 0.5$ at the top of the pedestal. Here, $R$ is the major radius, $\epsilon (\equiv a/R)$ is the inverse aspect ratio, $a$ is the minor radius, $q_{95}$ is the safety factor at the 95% flux surface and $\lambda_e = v_{Te} \tau_e$, the product of electron thermal velocity $v_{Te}$ and electron-electron collision time $\tau_e$. At 2000 ms, we reduce the initial torque input from the neutral beams towards a balanced beam input, while keeping the NBI beam input power close to 3 MW (figure 1 and figure 2). The experiments presented in this paper were performed on different days and we show the time evolution of the main characteristics in two separate figures to highlight that the plasma conditions and input parameters were similar (figure 1 and figure 2) on both experimental days. In order to increase the ratio of electron temperature over ion temperature ($T_e/T_i$), we replace part of the NBI heating (black time trace) with ECH in separate discharges (red and blue time traces). Using ECH increases $T_e$ in the plasma core, which in turn increases the electron temperature gradient, $1/L_{Te}$. This results in a strong reduction of the line averaged density, and in order to avoid a back transition to L-mode, we have to add a gas puff, depending on the wall conditions (figure 1 and figure 2).

Applying ECH heating in these low density plasmas allows us to increase the $T_e/T_i$ ratio from 0.7 to 2.0 [figure 3(a)]. Previous work in AUG has shown an increase in
density peaking with increased $T_e/T_i$ ratio [5, 9]. In these DIII-D H-mode plasmas, we have not observed such a trend [figure 4]. Using the reflectometer to measure the electron density, we observe a strong overall reduction in the density profile [figure 3(b)]. The density loss is not just located at the plasma edge, but also in the plasma core. However, in order to make a prediction as to how particle transport changes, we first need to address the changes in particle balance, owing to changes in the NBI core fueling.

In order to assess whether the changes in the density profile are purely the result of a change in fueling, we need to look at the particle balance $\frac{\partial n}{\partial t} = -\nabla \cdot \Gamma + S$, where $n$ is the density, $t$ is the time, $\Gamma$ is the particle flux and $S$ is the particle source. In figure 1, the ECH heated plasma received an additional gas puff to maintain H-mode confinement, while the NBI fueling is reduced by 50%. In figure 2, no such increase in gas puff is needed to keep the ECH heated plasma in H-mode, due to slightly different wall conditions in comparison with the discharges in figure 1. Not accounting for the amount of fueling from the walls, which is difficult to assess, especially without any information on the amount of particles being lost to the cryo-pump, the amount of fueling in the ECH heated plasma was 50% higher (12 TorrL/s) versus the NBI heated plasmas (8 TorrL/s) in the worst case example shown in figure 1. At the same time there is a reduction in the line averaged density from $3.5 \times 10^{19} \text{ m}^{-3}$ in the NBI-heated plasma to $2.0 \times 10^{19} \text{ m}^{-3}$ for the ECH-heated plasma. The combination of increased fueling and reduced density means that overall particle transport increases.

Assessing how fueling from the wall changes in these discharges is difficult. The strike-point is in the optimal location for pumping, but without pressure measurements in the pump plenum it is not possible to assess where the outflux of particles is ending up. There is no increase in $D_{\alpha}$ light in the divertor area, which is an indication that recycling in this area does not increase. Examining the extremes from where the gas puff fueling (gas valve is located close to the top of the plasma on the low field side) does not fuel the plasma to where the gas puff fully fuels the plasma, this leads to an increase in outward particle flux from 7% to 60% at the edge. In other similar plasmas, in which we did not need to add an additional gas puff (figure 2), a gas balance assessment using the same limitations as described in this paragraph results in a 33% increase in particle flux at the plasma edge.

Another way to approach this problem of particle balance is to look at the changes in particle flux $\Gamma$ [figure 5(a)] and compare these to changes in the density gradient. We observe that a reduction by 50% in core fueling results in a reduction of the particle flux by about 50% in the core of the ECH-heated plasma as calculated with the 1.5D transport code ONETWO. ONETWO does not have a reliable model to capture the effects of edge fueling, so the results closer to the plasma edge will not correctly capture
the changes in experimental particle flux. If we assume that particle transport does not change, then all the changes in $\Gamma = -D \frac{\partial n}{\partial r}$ are the result from a change density gradient, not a change in $D$, the effective diffusion coefficient. Figure 5(b) shows that the density gradient is not reduced by 50% over the plasma core. There is a very strong reduction close to the magnetic axis by about 75%, but close to mid-radius, both gradients are very similar. As a result, $D$, the effective diffusion coefficient will not be the same in the ECH-heated discharge and the NBI-heated discharge [figure 5(c)]. This shows that the changes in the density profile are the result of changes in transport, not just the result of changes in core fueling and that these changes in transport are different at different radial locations.

As a final measure for the changes in transport, figure 6 shows $1/L_N = \nabla n/n$ as a function of radius for an NBI-heated discharge versus an ECH-heated discharge. $\nabla n/n$ is often used as a measure for the ratio of inward pinch over outward diffusion $v/D$ (this is assuming that fueling is negligible). From $\rho \sim 0.3$ and outward, there is nearly no difference between the ECH-heated discharge and the NBI-heated discharge. This would suggest that the ratio of $v/D$ does not change, but the individual components could change. In the next section we will look more closely at the measured changes in particle transport.

3. Changes in particle transport

In order to assess the changes in particle transport, we use a perturbative gas puff technique. This technique has been successfully used to address the changes in particle transport as a result of resonant magnetic perturbations (RMPs) and collisionality in DIII-D plasmas [4, 14]. Other devices, such as LHD and JET have also recently used the mathematical derivation by Takenaga et al. [15] to study particle transport [16, 17]. By applying a small perturbative gas puff, we modulate the density profile with a fixed modulation frequency. Using Fourier analysis we can extract the phase and amplitude of this modulation. Fourier decomposing the perturbed continuity equation, the perturbed diffusion coefficient, $D_p$ and the perturbed convection coefficient, $v_p$ can be expressed in terms of this amplitude and phase. We refer the reader to these previous publications and the original paper by Takenaga et al.[15] as well as early work in the 1990s on perturbative transport techniques for the equations and the full derivation [18, 19, 20, 21]. Using this technique we can extract the perturbed transport coefficients for the NBI-heated plasmas as well as the ECH heated plasmas (figure 7). Figure 7 shows that the changes in transport are not just restricted to the diffusion coefficient, $D_p$, but also affect the inward pinch, $v_p$ (with a negative value pointing to an inward pinch). Up to $\rho = 0.5$ the changes in $D_p$ and $v_p$ of the ECH-heated plasma in comparison
Particle transport in low-collisionality H-mode plasmas on DIII-D
to the NBI-heated plasma are small and mostly restricted to a small increase in $D_p$. From $\rho = 0.5 - 0.65$ the more pronounced increase in outward diffusion with ECH is countered by a strong increase in a inward pinch. Outside $\rho = 0.65$, the strong increase in outward diffusion and the reduction in the inward pinch, result in a strong increase in outward transport in the ECH-heated plasmas, as expressed by the $v_p/D_p$ fraction. We only show the result up till $\rho = 0.8$, because the perturbative transport analysis does not yet include the perturbative neutral fueling source, which will strongly affect the results at the plasma edge. We can compare these absolute ratios of $v_p/D_p$ to the inverse density gradients in figure 6. We observe that from $\rho = 0.3 - 0.6$ for both the absolute value of $v_p/D_p$ and the inverse density gradient there is little difference between the ECH-heated and the NBI-heated plasma. However, the slopes of the inverse density gradient are not the same. Outside this region, there is no similarity between the $v_p/D_p$ behavior and the inverse density gradient. Part of the difference in the core can be explained by the fact that in this comparison we neglect the effect of the fueling source from the beams ($\int S/Dn$). Including this parameter will improve the comparison between the perturbed transport coefficients and the inverse density gradient inside $\rho = 0.3$. However, for $\rho = 0.6 - 0.8$ fueling should not play an important source in the comparison. Considering that these transport coefficients have been obtained using a perturbative technique, a match should not have be expected, since the perturbed transport coefficients might not be the same as the background transport coefficients.

The gas puff perturbs the density profiles and depending on the gas puff size, as well as background transport and the radial location this can be on the order of 15% (the goal is to minimize the perturbation, while still obtaining good enough data to extract an amplitude and phase from the fourier analysis). The amplitude of the perturbation is not constant across the plasma radius, which means that the local density gradients are affected. The 'cold' gas puff will also affect the electron temperature, which will affect the electron temperature gradient. It is not yet clear how much these changes in local gradients will affect the background transport. Recent results from JET show that when the size of the gas puff is doubled, the amplitude doubles, while the phase is not affected [22]. This would indicate that the changes in local gradients does not affect the perturbed transport coefficients and that the perturbative coefficients might be very similar to the background transport coefficients in certain plasma regimes.

In order to compare these perturbative transport results with turbulent particle transport we use the Trapped Gyro-Landau Fluid (TGLF) transport code. TGLF is an eigenvalue code that solves the gyro-Landau fluid equations and includes the effects of shaped geometry via the Miller equilibrium model [23]. Also included are trapped particle physics, collisions, ExB shear; the code spans ITG/TEM wavelengths as well as
short wavelength ETG modes. Figure 8 shows the particle flux as a function of \( k_\theta \rho_s \), where \( k_\theta \) is the wave number and \( \rho_s \) is the ion sound gyro radius. The turbulent particle flux is calculated in a similar way as linear growth rates are calculated and based upon experimental profiles as input. Integrating over \( k_\theta \rho_s \), shows that although the peak in the normalized particle flux has shifted to higher \( k_\theta \rho_s \) in the ECH-heated plasmas at \( \rho = 0.5 \), the integrated particle fluxes for the ECH and NBI cases are similar. Further out at \( \rho = 0.74 \), there is a large increase in normalized particle flux for the ECH-heated plasmas in comparison with the NBI-heated plasmas. This observation is in agreement with the experimental changes in the perturbed \( D_p \) and \( v_p \) transport coefficients as well as the increase in steady-state particle flux. This motivates us to look more closely at the changes in turbulence in the next section.

4. Turbulence changes

To better understand how macroscopic transport is changing in these plasmas we have to look at the changes in turbulence characteristics. From figure 3(a) we see that changing the heating from NBI to ECH changes the \( T_e/T_i \) ratio. As a result, in these low collisionality ECH-heated plasmas the turbulence regime will be dominated by the electron temperature gradient. Figure 9 shows that the frequency of the largest growth rate changes from the ion to the electron direction in the ECH-heated plasmas, whereas for the NBI-heated experiments the mode frequency remains in the ion direction. This is an indication, that based on linear stability analysis the plasma switches from being ITG dominant to TEM dominant close to mid-radius. This switch from the ion to the electron direction will change the thermo-diffusion component of the turbulent particle flux from inward to outward. The radial location where we observe the changes in turbulence is in agreement with radial location where the perturbative diffusion and pinch coefficients have the largest changes, even if the \( v_p/D_p \) ratio is unaffected.

More detailed linear gyrokinetic simulations with TGLF from \( \rho = 0.35 - 0.75 \) show that in the case of the NBI heated plasmas, that the peak of the linear growth rate is close to \( k_\theta \rho_s \sim 0.35 \) [figure 10(a)]. Outside \( \rho = 0.7 \), there is a clear shift to higher \( k_\theta \rho_s \) values. At the same time, we find that the frequency of these modes is in the ion direction for \( \rho < 0.7 \) and in the electron direction further out [figure 10(b)]. For the ECH heated discharges, the largest growth rates occur at \( k_\theta \rho_s \sim 1.2 \) [figure 10(c)]. The maximum value of the linear growth rates for the ECH heated discharge is about twice the value of that of the NBI heated discharge. As a result the linear growth rates for \( k_\theta \rho_s \) 0.5 – 1 are of the same magnitude in both discharges. In the ECH heated plasmas, the frequency of the modes is in the electron direction from \( \rho = 0.47 - 0.75 \).

Experimentally, there is an increase in mid-range \( k_\theta \rho_s \sim 1.5 - 3 \) density fluctuations
in the ECH heated plasmas in comparison with the NBI heated plasmas as measured with the Doppler Backscattering (DBS) [24], as seen in figure 11. This increase in mid-range fluctuations can mean that there is a shift to higher $k_{\theta}\rho_s$ turbulent structures, or that there is a global increase in turbulence. Without fluctuation measurements at different wave-lengths, it is impossible to assess experimentally whether this is a global increase in turbulence, or whether this is a shift to higher $k_{\theta}\rho_s$.

5. Discussion

In this paper we have shown that by increasing the $T_e/T_i$ ratio, along with the local temperature gradients, we get a strong density pump-out. This increase in $T_e/T_i$ changes the linear stability from dominantly ITG in the NBI-heated plasmas to dominantly TEM in the ECH-heated plasmas. This change in the turbulence group velocity is predicted to increase the thermodiffusion component of the particle flux. TGLF simulations confirm this increase in particle flux. However, this is counter to observations on AUG [5]. DIII-D and AUG are very similar machines, with the exception of the first wall material. Recent results on JET with the new ITER Like Wall (ILW) show that the new wall not only affects the pedestal density, but also changes core density gradients [25]. This is an indication that the role of the first wall material can play a role in determining the peaking of the density and might be a reason as to why the DIII-D and AUG results are so different. A more careful database like analysis of the DIII-D experiments in needed to make a more direct comparison to AUG results.

Another important observation is that although linear gyrokinetic simulations show that we transition from an ITG to a TEM-dominated regime around mid-radius, the typical rotation reversal or even a strong reduction in the toroidal rotation is not observed (figure 12). The only changes in toroidal rotation are in the plasma core and in the plasma edge. The change in the edge rotation was observed in every discharge in which ECH was applied, whereas the change in the core rotation did not follow a clear trend. Adding a gas puff in the ECH heated plasmas to restore the pedestal density of the NBI-heated plasmas, resulted in the return of the ‘well’ in the edge toroidal rotation. As a result, one could question whether the plasma actually transitions from ITG to TEM. However, recent publications with relation to the rotation reversal show that they do not solely depend on local linear ITG-TEM transitions [10, 11].

Moreover, in AUG these ITG-TEM transitions also result in an increase in density peaking. We did not observe an increase in density peaking and especially not an increase in particle confinement, which would be beneficial to ITER and future tokamaks. These sudden increases in particle confinement in AUG are associated with the observed rotation reversals. In DIII-D, a pure transition from ITG to TEM does not increase
the peaking and thus this begs the question whether the rotation reversal is a necessary condition in order to increase density peaking.

6. Conclusion

In this paper we show that a change in turbulence regime (based on linear gyrokinetic simulations) from ITG to TEM results in a strong density pump-out. The reduction in the density cannot be explained by a reduction in core fueling. This is in agreement with theory which predicts an increase in outward particle flux when turbulence group velocity changes sign. TGLF simulations as well as perturbed transport coefficients show a strong increase in particle transport outside $\rho = 0.6$. We find that in the region in which linear stability predicts a change from ITG to TEM, there is a strong increase in the diffusion coefficient. A comparison between $v/D$ and the inverse density scale length shows we need to include the effects of the neutral beam fueling source in the core to get a fairly good match. Intermediate scale fluctuations show a strong increase outside $\rho = 0.6$, as might be expected when the plasma transitions to the TEM regime. We do not observe the typical rotation reversal or reduction in the toroidal rotation associated with ITG-TEM transitions. Future work will focus on understanding the role of the toroidal rotation gradient and collisionality upon particle transport. In order to better understand how these turbulence changes affect toroidal rotation, we will compare perturbative beam modulations with changes in momentum transport.

Figure 1. (Color Online) Time evolution of three representative discharges in which the heating was changed from (a) NBI (dashed lines) to ECH (solid). (b) Shows the evolution of the density of the ECH (red and blue) and the NBI (black) heated discharges. In order to limit the density reduction for the ECH discharge, a gas puff is added (red) in another ECH discharge a gas puff is added to match the density from the NBI heated discharge (c). (d) shows the injected torque for both discharges and (e) has the resulting core (solid) and edge (dashed) carbon toroidal rotation.

Figure 2. (Color online) Time evolution of two representative discharges in which the heating was changed from (a) NBI (dashed lines) to ECH (solid). (b) shows the evolution of the density of the ECH (red) and the NBI (black) heated discharges. In order to limit the density reduction for the ECH discharge, a gas puff is added (c). (d) shows the injected torque for both discharges and (e) has the resulting core (solid) and edge (dashed) carbon toroidal rotation.
Figure 3. (Color online) (a) $T_e/T_i$ ratio for an ECH-heated discharge (red) and an NBI-heated discharge (blue) versus $\rho$. These curves are based on polynomial fits to the ion temperature measured with CER and the electron temperature measured with Thomson scattering as well as ECE. (b) The electron density polynomial profile fits using the profile reflectometry as a function of $\rho$. A strong reduction in the overall density profile is observed in the ECH-heated (red) plasma in comparison to the NBI-heated plasma (blue).
**Figure 4.** (Color online) Database of discharges in which the $T_e/T_i$ ratio was varied by adding ECH heating as a function of the maximum inverse density gradient ($1/L_n$) in the core plasma. The radial location of the maximum inverse density gradient can vary.

**Figure 5.** (Color online) (a) Particle flux calculated with ONETWO for an ECH (red) and a NBI (blue) heated plasma. The particle flux is over the core region about a factor 2 lower for the ECH-heated discharge, due to a lower core source from the neutral beams. (b) The density gradient for the same ECH (red) and NBI (blue) discharge does not show the same average factor 2 decrease in the core. (c) The effective diffusion coefficient based on the ONETWO flux and the experimental density gradient for the NBI (blue) and ECH (red) discharge.
Particle transport in low-collisionality H-mode plasmas on DIII-D

Figure 6. (Color Online) Inverse density gradient, $1/L_N$, as a function of $\rho$ shows that the NBI (blue) heated discharge is much more peaked in the core, due to core fueling from the beams. The ECH (red) heated discharge is more peaked outside $\rho \sim 0.3$.

Figure 7. (Color Online) Perturbed transport coefficients obtained using a perturbative gas puff. (a) The perturbative diffusion coefficient increases strongly outside mid-radius for the ECH (red) heated plasma versus the NBI (blue) heated plasma. (b) Part of the increase in outward diffusion is countered by an increase in inward pinch just outside mid-radius in the ECH-heated plasmas. (c) The $v/D$ ratio shows that the increase in transport for the ECH-heated plasma occurs mostly outside $\rho \sim 0.6$. 
Figure 8. (Color Online) Calculated $\Gamma/\Gamma_{GB}$ using TGLF for NBI-heated (blue) and ECH-heated (red) plasma at two radial locations $\rho = 0.5$ (dashed) and $\rho = 0.74$ (solid). The particle flux moves to higher $k_\theta \rho_s$ for the ECH-heated plasma, but the integrated flux only increases at $\rho = 0.74$.

Figure 9. (Color Online) Frequency of the largest growth rate using GKS shows a cross-over from ITG to TEM for the ECH-heated (red) discharge close to mid-radius. The NBI-heated (blue) discharge remains in the ITG regime over the whole radius.
Particle transport in low-collisionality H-mode plasmas on DIII-D

Figure 10. (Color Online) Contour plots showing the linear growth rate (a and c) and corresponding frequency (b and d) using TGLF for an NBI and an ECH heated discharge from $\rho = 0.35 - 75$ for low and intermediate $k_0\rho_s$ scales. The maximum linear growth rate in the ECH heated plasma is twice that of an NBI heated discharge and has shifted to higher $k_0\rho_s$. The frequency for the ECH heated discharge is in the electron direction from $\rho = 0.5$ for all $k_0\rho_s$, whereas the frequency is in the ion direction for all $k_0\rho_s$ for the NBI heated discharge.

Figure 11. (Color Online) Intermediate scale density fluctuations measured with the DBS for an ECH-heated (red) versus an NBI-heated (blue) discharge. There is an increase in $\tilde{n}/n$ from mid-radius outward for the ECH-heated discharge, which is an indication of an increase in TEM size turbulence.
Figure 12. (Color Online) Carbon impurity toroidal rotation profiles as a function of $\rho$ for an ECH-heated (red) and an NBI-heated (blue) discharge. No rotation reversal is observed, only a flattening of the profile in the core and the 'well' in the edge rotation dissapears with ECH heating.
